ACKNOWLEDGMENTS

The author expresses his appreciation for the work and support of MSgt Jorge Noverola and SSgt Robert P. Davis in conducting the survey. The Civil and Bioenvironmental Engineering staff at Eielson AFB were helpful and generous with their time, and essential for the completion of this project. Bioenvironmental Engineering staff provided photos for documentation of the height of the infiltration pond water. Chris Lidstone, of Lidstone & Anderson, Inc., generously provided engineering consulting support for this project.

EIELSON AIR FORCE BASE, ALASKA, INFILTRATION POND STUDY

INTRODUCTION

The USAF Armstrong Laboratory, Occupational and Environmental Health Directorate, Bioenvironmental Engineering Division, Water Quality Branch (AL/OEBW) was requested by 354 CES/CEV, Eielson AFB (EAFB), Alaska (AK), to conduct a survey of the infiltration basin at the base's wastewater treatment plant (WWTP). The effluent water from the WWTP discharges to the infiltration pond at an average rate of approximately one million gallons per day (1 MGD). The infiltration basin is a former gravel pit of approximately 18-20 acres in size. Appendix A provides a site location map showing the infiltration basin and its position relative to the WWTP.

Recently, the pond has been enlarging, and on occasion overflowing onto Central Avenue near the main entrance of the base. In May 1995, EAFB Civil Engineering Squadron (CES) personnel requested OEBW to determine if the infiltration pond has a sludge or soot layer "plugging" the bottom of the pond and causing the overflow conditions. OEBW's goal during the 24-28 July 1995 survey was to determine the nature and extent of such sedimentation, characterize the material for disposal alternatives, and identify ways to prevent future overflowing.

SAMPLING METHODOLOGY

OEB personnel used a row boat belonging to the treatment plant to access the infiltration pond. To determine the nature and extent of possible sedimentation, OEB planned to use a sludge judge to measure the depth of the muck on the bottom of the pond at several locations. At each point measurements of water depth would be taken and a core sample of the sediment drawn with either the sludge judge or a ponar dredge (See Appendix D for diagrams of the sampling equipment). The anticipated depth of the water was 10 feet. On-site conditions made the use of the sludge judge impossible, because the water depth was between 15 and 25 feet across the majority of the pond, and the sediment was too consolidated for the sludge judge to penetrate. Thus, OEB could not obtain an accurate measurement of the thickness of the sediment. OEB also had a seven foot long sediment coring tool, but the depth of the water prevented the use of this equipment.

In order to characterize the sediment for disposal alternatives, equal amounts of sludge samples from each sampling location were collected with a ponar dredge and placed into a large glass jar. This composite sample was thoroughly mixed, and aliquots taken and placed in the appropriate sample containers for Toxicity Characteristic Leachate Procedure (TCLP) analyses. The TCLP procedures included metals, pesticides, herbicides, volatile and semivolatile organic compounds, and reactivity. OEB personnel took duplicate samples for quality control purposes to insure the reproducibility of the analytical results.

To assess the permeability of the sediment, OEB personnel attempted to conduct an on-site test. In this procedure, water is placed on top of a column of the sediment, and the time for the water level in the test column to fall a specified distance is measured. Figure 1, below, illustrates the method.

**FIGURE 1.
FALLING HEAD PERMEABILITY TEST**

The hydraulic conductivity of the soil, k , is calculated by the equation, $k = L/t \ln(h_0/h_1)$, where t is the amount of time it takes the water level to drop from h_0 to h_1 (Adapted from Freeze & Cherry, 1979), and L is the length of the soil column.

The low conductivity of the sample, however, made it impossible to conduct this test in the field because there was no visible migration of the water through the sludge column. Thus, OEBW sent a batch of the sludge to the Soil and Crop Science laboratory at Texas A&M University. In a similar test, Texas A&M placed an aliquot of the sludge into a plastic double ring infiltrometer, designed by McNeal & Reeve (1964). Water was loaded on top of the sample, and the effluent water volume measured over the course of 5 days to determine the hydraulic conductivity of the sludge. See Appendix B for the laboratory report of the permeability test.

RESULTS AND DISCUSSION

Figure A-1 of Appendix A shows the site location map for the WWTP infiltration basin. It was apparent during the survey that the infiltration pond has become larger than it has historically been. Figure A-2 Shows the approximate shoreline location during the survey. A barbed wire fence around the original perimeter of the pond was almost completely submerged in the water at the time of this survey. WWTP personnel indicated that this fence was entirely above the water in the past. Figures A-3, A-4, and A-5 of Appendix A provide photos taken on 28 September 1995, which show how the water extends beyond the fence line. OEBW believes that the water level was higher during the survey than at the time of these photographs, but does not have pictures for comparison.

Figure A-6 shows the approximate location of sediment samples, and the water depth at each location. The sediment in the infiltration basin was dark green in color and had a mild odor of decaying biological matter. The character and consistency of the sediment was fairly constant throughout the pond, except at locations to where the pond had recently extended. At these locations, OEBW observed significant amounts of coniferous needles, leaves, sticks, and bark or grass, and little collectible sediment. These locations were near the edges of the pond where tree stumps and the surrounding barbed-wire fence protruded from the water. This information, along with past aerial photos, indicate that the pond has not always covered these areas, and that it is, indeed, increasing in size.

All analytes of the Toxic Characteristic Leachate Procedure sediment tests were below regulatory limits. These results indicate that disposal of any dredged material from the pond should

not require any special considerations, because it is non-hazardous. Appendix C provides the analytical results from the laboratory.

The hydraulic conductivity of the pond sediment is on the order of 10^{-5} to 10^{-6} cm/sec. This is in the general range of silt/loess, glacial till, or limestone, dolomite, and sandstone rocks. In comparison, sand and gravel, or karst limestone have conductivities on the order of 1 to 10^{-2} cm/sec (Freeze and Cherry, 1979). Also, 10^{-6} cm/sec is the conductivity often required for material lining a landfill. This indicates that the sediment in the bottom of the infiltration basin is impermeable relative to the underlying sand and gravel. The laboratory results indicate that the conductivity of the sediment might even be less than 10^{-6} cm/sec for a consolidated sample (the sample that OEB submitted to the laboratory was disturbed). The results in Appendix B show that through the duration of the test, the conductivity was decreasing, which is likely due to consolidation of the material.

The water in the pond was dark green in color, apparently due to algal growth. Total suspended solids in the WWTP effluent average about 15 mg/L, which equates to about 8500 pounds of solids per year. The build-up of sediment in the bottom of the effluent pond is likely due to both algal growth and the settling of suspended solids in the effluent water.

Water will flow from the infiltration pond to the underlying water table because the hydraulic head of the pond is greater than the surrounding groundwater. OEB personnel did not measure the elevation of the pond surface relative to the levels of the surrounding water table. Even without this data, however, we can estimate the head required to push 1.0 MGD of water through soil with a hydraulic conductivity of 10^{-6} cm/sec. The size of the pond is approximately 20 acres, with depths ranging up to about 25 feet. OEB personnel could not precisely measure the depth of the sediment in the basin because of the lack of proper sampling equipment, but based on the information we obtained with the sampling dredge and sludge judge, the sediment is at least 4 inches thick across the majority of the pond. Using Darcy's flow equation, which states that flow through a porous media is proportional to the hydraulic conductivity of the media and the head gradient forcing the flow, 7.1 feet of head difference would be required to push one million gallons per day of water into the underlying groundwater. Based on visual observations of nearby ponds not directly receiving wastewater, the hydraulic gradient is no more than a couple of feet over less than a hundred feet (i.e., the surface of the infiltration basin is very close to the surrounding groundwater levels).

Another significant loss of the water can come from evaporation and evapo-transpiration. One million gallons of water per day, spread over 20 acres, equates to a layer about 0.15 inches deep per day (55 inches per year). The annual net precipitation in the Fairbanks area is about one inch per year (12 inches precipitation and 11 inches evapo-transpiration), so evaporation may constitute a significant portion of the wastewater disposal during dry periods (but not on a yearly average). The evaporation rate is not constant throughout the year and depends on water temperatures, atmospheric temperatures, wind speeds, and relative humidity. At times, water may condense onto the pond surface rather than evaporate from it.

Because of the lack of hydraulic potential and the low conductivity of the pond sediment, the pond is enlarging to accept the 1,000,000 gallons per day of water. The effect of the increase in size is dual: the increase in bottom area provides more space for infiltration and the larger surface area allows for increased evaporation. The land surrounding the infiltration basin is more permeable than the main part of the basin, because it does not have a buildup of low conductivity sediment. In addition, if the soil surrounding the pond boundaries is not saturated with water, capillary suction will increase the infiltration rate at the edges of the pond. Thus, small increases in the pond size might significantly increase the infiltration rate.

Another important consideration is the effect of permafrost on the infiltration capacity and other characteristics of the basin. Surrounding permafrost may inhibit percolation of the water into the surrounding soil, further contributing to the enlargement of the infiltration pond. The effect of permafrost on the migration of contaminants through the groundwater should also be considered in any detailed studies of the WWTP effluent water quality. Surrounding groundwater monitoring wells have shown concentrations of metals, ammonia, and nitrates, potentially from the wastewater, but, as stated before, the sediment did not show evidence of contamination. Metals in this water may also come from background (natural) sources.

CONCLUSIONS

The infiltration pond at EAFB has a significant layer of relatively impermeable sediment which appears to be due to several years' worth of biological (algae) and suspended solids (TSS) settling and sedimentation. This sediment is likely a contributing factor to the increase in area of the infiltration pond because it is essentially plugging up the system. Below are listed several options to approach the problem of the enlarging infiltration pond.

Options

1. EAFB could dredge the sediment from the bottom of the infiltration basin, effectively increasing the capacity of the basin to accept the wastewater. The dredged material is non-hazardous and should not pose a disposal problem. Assuming that there are four inches of sediment stretching over about 15 acres (tree stumps cover the shallow parts of the pond), about 8100 cubic yards of material would need to be removed. This material would increase in volume due to the unconsolidating effect from dredging, but has a high water content, and may compact significantly with dewatering. Because of the non-hazardous nature of the material, it could be disposed of by land application. The specifics of the disposal would need to be coordinated with the state, regardless of the non-hazardous nature of the material.

2. An alternative to dredging and removing the material would be to scrape the bottom of the basin with some sort of drag link to break up the consolidated material, thus 'unplugging' the system. Breaking up the compacted layers of the sediment would increase the permeability and increase the capacity for the basin to accept the wastewater. This would be a short-lived solution because the material would eventually re-deposit on the bottom of the pond and need scraped again.

3. In order to increase the head potential driving the water into the underlying groundwater, and to eliminate flooding, EAFB could construct a berm around the perimeter of the pond, which would essentially increase the depth of the basin. This would also require that the piping which brings the effluent to the infiltration pond be redone to be compatible with the higher water surface. This option would not eliminate the muck, or the formation of more layers of muck on the bottom of the pond, but would enhance the infiltration through the sediment by increasing the driving potential. CH₂MHill estimated, in a January 1995 report, that this project would cost approximately \$200K. If the pond were also dredged, the sediment could be used for berm material after dewatering. This would eliminate most disposal concerns.

4. EAFB could dispose of the wastewater effluent to a local waterway, such as Garrison Slough. This would eliminate the problem of the pond water flowing onto the base road (unless flooding is due only to water table fluctuations). This option, of course, would require the treatment plant to complete an application for a NPDES permit and to consider the impact of the effluent on the waterway. The historical analytical data for the wastewater might be adequate for developing such a permit. The plant would also have to construct adequate piping to direct the flow to the slough.

One concern with this option is that high ammonia and nitrate levels in the wastewater might be detrimental to the receiving waterway. For this reason, a denitrification process might have to be added to the treatment process at the plant. However, nitrates migrate easily in groundwater, and have already been found at high levels in monitoring wells near the effluent pond. Migration of this contamination to nearby waterways might occur in the near future, stemming a requirement to control nitrate levels in the wastewater effluent anyway, regardless of whether EAFB discharges directly to the waterway or indirectly via infiltration to groundwater.

5. In addition to any of the above options, EAFB could propose to the State of Alaska the use an algaecide (such as copper sulfate) to reduce the algal formation in the basin. The thick impermeable sediment on the bottom of the pond appears to be due to buildup of biological mass, most likely algae, over several years. The muck is dark green in color and has the odor of decaying biological matter. The rate of sedimentation could be reduced by limiting algal growth.

6. EAFB could install several (6-12) stand pipes to handle overflow conditions. Figure 2, below, illustrates this option. The stand pipes would be 12 to 24 inch diameter pipes set below the impermeable layer. The section of the pipe below the sediment layer would be screened or slotted to allow migration of water through this section. When the pond levels reach the height of the influent slots on the stand pipe, the water would percolate into the underlying strata. The bottom sediment would have to be cleaned from the standpipe before the pipes would operate properly. These pipes could be installed near the shore line.

FIGURE 2.
STAND PIPE DIAGRAM

7. One other item worth discussion is denitrification of the wastewater. If EAFB continues to dispose of the WWTP effluent into the infiltration basin, denitrification of the wastewater would reduce the algal nutrient levels in the water. This would lessen the extent of algae formation and reduce the rate of sedimentation. In addition, this additional treatment step would reduce the TSS levels in the wastewater, providing even further reduction in the sedimentation rate in the basin. If EAFB chooses to dredge or scrape the basin, the reduced sedimentation rate would increase the interval between such operations.

8. EAFB could take no action at this time except to monitor the levels of the pond for at least one year. During the spring season of 1995 EAFB experienced unseasonably warm weather and rapid melting of snow and ice. OEB personnel were TDY to Eielson in April 1995 and witnessed several feet of snow melt in less than one week. This might have been a cause of a rapid increase in ambient water table levels, which would have decreased the capacity of the infiltration basin to accept the wastewater, thus causing it to enlarge. Monitoring the levels of the effluent pond relative to the

surrounding groundwater would give insight into the extent of the problem due to the sedimentation, and that due to natural groundwater fluctuations.

RECOMMENDATIONS

At this time, OEBW recommends that EAFB follow Option 8, described above. EAFB should install some sort of datum pole to gage the level of the water in the infiltration basin, and take weekly or bi-weekly readings throughout the course of a year or more to determine trends in the level. This data can be compared with plant flow rates and surrounding monitoring well levels to better determine the driving factor causing the pond to enlarge. Obviously, as the pictures of the pond show, the pond has increased in size well past the fence line. It is difficult to determine how much influence the sedimentation in the pond has on the increase in size as compared to the influence of ambient groundwater levels and evaporation rates. OEB also recommends discussing the available options with the state, allowing the state an opportunity to respond or recommend a course of action.

If the State of Alaska requires EAFB to take some action immediately, OEB recommends constructing berms around the pond and/or dredging or scraping the bottom of the pond to increase the infiltration capacity and to prevent flooding. These actions would be more easily implemented than changing the discharge to a nearby waterway.

If EAFB wishes to gain a better understanding of the hydrogeology of the pond, and obtain a more detailed study of the options for wastewater disposal, OE maintains five on-line contractors who could be used to conduct such studies. OEB appreciates the opportunity to work with Eielson Air Force Base and Pacific Air Forces.

Dear Lt. Franapfel:

As per your phone request and letter of August 10, I have measured the permeability of the muck sample which you submitted. The procedure which was used and the results obtained are as follows:

Procedure:

Muck was removed from the container and placed in a plastic double ring infiltrometer designed by McNeal & Reeve (1964). The inside diameters of the inner and outer rings were 2 and 3 inches, respectively. Muck was added to a finished depth of 1 3/4 inches with very light compaction sufficient only to settle the material. Water was added to a depth of 2 3/8 inches above the soil surface. Effluent from the center ring was collected and measured twice per day. The depth of water was also measured and used to calculate the hydraulic conductivity. All calculations are based on the volume of muck above the inner ring and a total porosity of 50% was used as an estimate of one pore volume.

Results

The hydraulic conductivity as a function of pore volume is presented in the following table and is shown graphically in the attached figure.

<u>Date of Measurement</u>	<u>Cumulative Pore Volume</u>	<u>Hydraulic Conductivity (cm sec⁻¹)</u>
8/21/95	0.2	6.5×10^{-5}
8/21/95	1.1	7.6×10^{-5}
8/21/95	1.7	6.5×10^{-5}
8/21/95	2.3	4.3×10^{-5}
8/22/95	3.6	3.0×10^{-5}
8/22/95	4.4	5.0×10^{-5}
8/22/95	5.1	4.7×10^{-5}
8/23/95	6.5	2.5×10^{-5}
8/24/95	7.5	1.2×10^{-5}
8/24/95	7.7	9.3×10^{-6}
8/25/95	8.1	6.1×10^{-6}

The sample had an initial hydraulic conductivity of about 6.5×10^{-5} cm sec⁻¹ over the first two pore volumes of effluent. Some particle migration was observed as sediment in the outflow tube and collection vessel. The hydraulic conductivity then showed a steady decrease until by the passage of 8 pore volumes of leachate the conductivity had decreased by 1 order of magnitude to 6.1×10^{-6} cm sec⁻¹.

Lt. Franapfel
August 28, 1995
Page 2

I attribute this decrease to a combination of some slight settling of the lightly compacted sample and the migration of fine colloidal particles into the pores where they inhibit the flow of water. Considerable swelling of the material was also observed over the test period. Thus, I would anticipate this sludge to have an initial conductivity in the range of 6×10^{-5} cm sec⁻¹ and that it may decrease by as much as one order of magnitude over time. It is also likely that larger decreases in conductivity could be achieved if the material were compacted after placement. It is also likely that the conductivity will be increased if the sludge is allowed to dry prior to placement.

I have returned the sludge to its original container and will retain the sample for 90 days in case you wish to have additional tests performed on it. An invoice in the amount of \$75 has been submitted to Clayton Environmental Services as per your instructions.

Please feel free to contact me if you have any questions or if I may be of further assistance.

Sincerely,

James C. Thomas

Page 16

Identification of major components employing any of the following:

Solubility Tests - Water, hexane, acetone
IR Spectra of Liquids and Vapors
GC/FID Screening and Fingerprinting
GC/MS by solvent dilution/direct injection

SW-846 Method 9045 (Electrometric) - pH

Test Methods for Evaluating Solid Waste - Physical/Chemical Methods
(SW-846) Third Edition, Proposed Update I, Section 7.3.3.2 - Cyanide Reactivity

Test Methods for Evaluating Solid Waste - Physical/Chemical Methods
(SW-846) Third Edition, Proposed Update I, Section 7.3.4.2 - Sulfide Reactivity

SW1311 (Bottle Extraction for Non-volatiles)

SW1311 (TCLP Rotary Extraction)
SW8080 (Pesticides)

SW1311 (TCLP Rotary Extraction)
SW8150 (Herbicides)

SW1311 (TCLP Rotary Extraction)
SW8270 (Semivolatile Compounds)

SW1311 (TCLP Extraction - ZHE)
SW8240 (Volatile Compounds, modified for megabore column)

SW1311 (Zero Headspace Extraction)
